Elk and cattle forage use under a specialized grazing system

LACEY E. HALSTEAD, LARRY D. HOWERY, GEORGE B. RUYLE, PAUL R. KRAUSMAN, AND ROBERT J. STEIDL

Abstract

The Walker Basin Allotment grazing system in central Arizona is designed to allocate resource use under elk (Cervus elaphus L.) and cattle (Bos taurus L.) grazing. The grazing system was designed to promote biologically acceptable levels of forage use on the half of the allotment scheduled for cattle grazing and to rest the other half by attracting elk to pastures recently grazed by cattle. The objectives of our 2-year study were to determine whether the grazing system facilitated proper forage use as defined by recent forage use and residual stubble height guidelines (i.e., 30 to 40% use and an 8- to 10-cm stubble height) and whether the system rested one half of the allotment from elk and cattle grazing. Mean (± SEM) total elk and cattle forage use for western wheatgrass (Pascopyrum smithii Rydb.), the key forage species, was 32 and 61% ± 7 in 1997 and 1998, respectively; corresponding mean (± SEM) stubble heights were 11 and 10 cm ± 0.6. Mean total cattle and elk forage use in 1998 (61%) exceeded the 30 to 40% use guidelines. However, mean end-of-year stubble height was never below 10 cm. The grazing system did not provide half the allotment with complete rest; elk used all study pastures. Elk use was higher in pastures with heavier tree cover and steeper terrain in both years, regardless of where cattle grazing occurred. Elk grazing patterns were apparently more dependent on tree cover and topography than any changes in forage caused by the grazing system.

Key Words: Arizona, deferred grazing, paired-plot, rest-rotation, stubble height, western wheatgrass

Specialized grazing systems have been developed that use cattle grazing as a tool to alter forage characteristics and, thereby, modify elk (Cervus elaphus L.) distribution. Such grazing systems often include elements of rest-rotation, deferment, or both (Vavra and Sheehy 1996). Improvements in forage availability, palatability, production, and/or animal performance have been suggested as advantages to using specialized grazing systems (Anderson and Scherzinger 1975, Alt et al. 1992, Wisdom and Thomas 1996). These systems may attract elk to areas recently grazed by cattle (Gordon 1988, Alt et al. 1992, Frisina 1992), or they may produce little or no change in forage production, nutritional content, or herbivore distribution (Lacey and Van Pooien 1981, Yeo et al. 1993, Wambolt et al. 1997).

The Walker Basin Allotment grazing system in central Arizona combines elements of rest-rotation and deferment, employing seasonal cattle grazing on half the allotment each year (United States Forest Service [USFS], unpublished Walker Basin Allotment Management Plan 1990, Camp Verde, Ariz.). The
objectives of our 2-year study were to determine whether the grazing system promoted target levels of forage use and residual stubble height (Holechek et al. 1998), and whether the system rested half the allotment from large ungulate herbivory each year.

Materials And Methods

Study Area
The Walker Basin Allotment (111° 40' 40' W, 34° 38' 30' N) is comprised of about 31,000 ha of USFS rangeland. The Walker Basin Allotment's 57 pastures are divided into 2 main sections that run west to east along an increasing elevational gradient. The Walker Basin Allotment has 3 seasonal ranges: winter (1,220 to 1,524 m elevation), transitional (1,525 to 1,982 m elevation), and summer (1,983 to 2,287 m elevation). Our study area (about 6,750 ha) consisted of 4 pastures (850 to 2,100 ha) on the transitional range (Fig. 1) because local resource managers identified this range as having high potential for elk and cattle competition (personal communication, USFS, Arizona Game and Fish Department, and ranch managers).

Western wheatgrass (Pascopyrum smithii Rydb.) has been identified by the USFS as the key herbaceous forage species in the study pastures (USFS, unpublished Walker Basin Allotment Management Plan 1990, Camp Verde, Arizona). Other plant species included blue grama (Bouteloua gracilis H.B.K.), sideoats grama (Bouteloua curtipendula Michx.), downy brome (Bromus tectorum L.), buckwheat (Eriogonum spp.), snake- weed (Gutierrezia sarothrae Pursh.), squawbush (Rhus trilobata Nutt.), emory oak (Quercus emoryi Torr.), pinyon pine (Pinus edulis Engelm.) and juniper (Juniperus osteosperma Torr.). Soils are predominantly classified as Vertic Haplustalfs (Terrestrial Ecosystem Survey of the Coconino National Forest 1992).

The growing season (frost-free days) on the transitional range extends from March to October. Average yearly precipitation is 33 cm, occurring primarily from December to February and July to September (National Oceanic and Atmospheric Administration 1997). Winter precipitation occurs primarily as snow. The northern pastures (1 and 2) were near an ephemeral drainage and contained more pinyon pine and juniper cover than the southern pastures (3 and 4).

Description of Grazing System and Herbivores
The Walker Basin Allotment grazing system is designed to promote biologically acceptable levels of forage use by cattle, elk, and other wild herbivores and to rest half of the allotment by attracting elk and other wild ungulates to pastures recently grazed by cattle (USFS, unpublished Walker Basin Allotment Management Plan 1990, Camp Verde, Ariz.). Hereford and Hereford cross-bred (Saler, Brford, Brahman, Angus, Gelbvieh) cow-calf pairs were used in this experiment and handled following the University of Arizona's Animal Care Protocol # 96-118. During 1997, 413 cow-calf pairs were used (mean body weight = 476 kg ± 62 SD), while 450 cow-calf pairs were used in 1998 (mean body weight = 457 kg ± 87 SD). Each year, cattle were moved up the elevational gradient through pastures on one half of the allotment during the growing season (about 14 days/pasture) and moved down the elevational gradient on the same half during the dormant season (about 5 days/grazed pasture). The other half of the allotment was rested from cattle grazing the entire year (i.e., rested pastures). Seasonal cattle grazing is used to increase palatable regrowth, which is hypothesized to attract elk to pastures recently grazed by cattle, thereby resting the other half of the allotment from cattle and elk herbivory.

According to the Arizona Game and Fish Department, elk is the main wild herbivore species that significantly impacts western wheatgrass, the key forage species used in this study. Jack rabbits (Lepus californicus Gray), pronghorn (Antilocapra americana Ord), mule deer (Odocoileus hemionus Rafinesque), and white-tailed deer (Odocoileus virginianus Rafinesque) are thought to use insignificant amounts of western wheatgrass compared with elk and cattle due to lower animal numbers or dietary differences (Thomas Britt, Regional Supervisor, Arizona Game and Fish Department, personal communication, Vavra et al. 1989). Thus, our research focused on elk and cattle impacts on western wheatgrass.

General Sampling Procedures
The study was conducted from March 1997 to October 1998. We estimated forage use by elk and cattle and residual stubble height during 2 growing seasons. The southern pastures (3 and 4) were grazed by cattle in 1997 and the northern pastures (1 and 2) were grazed by cattle in 1998 as required by the USFS grazing management plan (Fig. 1). Average stocking rates for cattle, calculated using definition 'a' of the Glossary Revision Special Committee report (1989), were 5.1 and 6.9 ha/AUM during 1997 and 1998, respectively (Fig. 1). All pastures were accessible to elk during the entire study.

Paired-plot and stubble height techniques (Interagency Technical Reference 1996) were used to evaluate grazing of western wheatgrass in 12 randomly selected 3-ha sampling areas (3/pasture). Each sampling area was located ≥ 0.4 km from well-traveled roads, fences, and water and ≥ 0.3 km from adjacent sampling areas. Sampling areas contained 6 paired-plot units. Each paired-plot unit consisted of 1 protected macroplot (1.7-m² grazing exclosure), and two, 1.7-m² unprotected macroplots, for a total of 72 protected and

Fig. 1. Study pasture layout on the Walker Basin Allotment, central Arizona. Cattle grazed southern pastures (3 and 4) Jun./Jul. and Nov. of 1997, and northern pastures (1 and 2) Jun./Jul. and Nov. of 1998. Elk had access to study pastures year-round.
144 unprotected plots in the study area (i.e., 72 paired-plot units). Two unprotected macroplots, rather than the traditional 1, were matched with each protected macroplot to account for possible patch grazing by cattle and elk (Klingman et al. 1943, Grelen 1967). Unprotected and protected macroplots were matched based on similar ocular estimates of western wheatgrass phytomass. Each sampling area also contained a 400-m stubble height transect located between protected and unprotected macroplots and ≥ 10 m from protected macroplots.

To avoid attracting animals to protected plots within sampling areas, each protected plot was ≥ 100 m from the others. Protected and unprotected plots were ≥ 50 m apart, and unprotected plots within a paired-plot unit were ≥ 10 m apart. To minimize bias due to enhanced growth within protected plots, new paired-plot units were established in March each year (Owensby 1969). Before initially establishing paired-plot units, we tested the precision of ocular matching by clipping, drying, and weighing western wheatgrass from 29 pairs of 0.25-m² circular plots that were later used to clip subsamples within paired-plot units. A paired t-test revealed no difference between paired test plots (P > 0.2, α = 0.05). The same observer always established paired-plot units.

We estimated forage use and stubble height in each pasture in 3 sampling periods: 1) immediately before cattle entered grazed pastures, 2) immediately after cattle exited grazed pastures, and 3) at the end of the growing season, about 3-4 months after cattle exited grazed pastures (Fig. 2 and Fig. 3; Tables 1 and 2). Measurements made before cattle grazed (early/mid-June) estimated relative elk use in all pastures. Measurements made after cattle grazed (mid-June/early July) estimated relative cattle and/or elk use, while measurements made at the end of the growing season (mid-October) estimated total forage use for the entire growing season (cattle and/or elk). Relative use describes the amount of forage consumed or destroyed up to a certain time during the growing season but prior to peak standing crop (e.g., June or July; Frost et al. 1994).

Total forage use is "the proportion of current year's forage consumed or destroyed by grazing animals," measured at the end of the growing season (Glossary Revision Special Committee 1989). Cattle grazed study pastures about 5 days in mid-November (dormant season), and elk migrating to winter ranges likely used study pastures at this time. However, we did not measure dormant season grazing because of snow depth.

**Paired-plot Sampling**

For each sampling period, we clipped western wheatgrass from 2 randomly selected paired-plot units in each sampling area within each pasture for a total of 24 paired-plot samples. All plots were clipped to ground level. During 1997, we used a 0.25-m² circular frame to clip 4 subplots within each 1.7-m² macroplot. We averaged the 4 subplot dry weights to obtain 1 mean protected weight for each protected macroplot. For the 2 corresponding unprotected macroplots, we averaged the 8 subplot dry weights (4 subplots x 2 macroplots) to obtain 1 mean unprotected weight. Percentage use for a paired-plot unit was the ratio of the mean unprotected and protected weights. Negative utilization values from paired-plot units were zeroed (Werner and Umess 1998). Mean use for a sampling area was calculated from the 2 randomly selected paired-plot units. Mean use for each pasture treatment (grazed or rested) was calculated across the appropriate 6 sampling areas for each sampling period (Table 1).

In 1998, we altered our paired-plot sampling procedure slightly to address the high range of variability of 1997 use estimates between paired-plot units within sampling areas (SE range = 0-35). For each paired-plot unit in 1998, we ocularly matched three, 0.25-m² subplots within the protected macroplot to three, 0.25-m² subplots within each of the 2 unprotected macroplots, creating 3 individually matched subsamples in each paired-plot unit. Percentage use for a matched subsample was the ratio of dry weights clipped from the 2 unprotected 0.25-m² subplots (averaged) and the corresponding 0.25-m² protected subplot. Percentage use for a paired-plot unit was the mean of the 3 matched subsample use estimates. Means for sampling areas and pastures were calculated as described in 1997. We calculated western wheatgrass standing crop dry weight (kg ha⁻¹) from protected macroplots each sampling period during both years of the study.

**Grazing animal (A) and year (B) effects on relative and total western wheatgrass forage use (%) across 3 sampling periods on the Walker Basin Allotment, central Arizona (SEM = 5).** *Sampling periods were: Before cattle grazing = relative forage use, early/mid-Jun.; After cattle grazing = relative forage use, mid-Jun./early Jul.; End of growing season, or 3 to 4 months after cattle exited grazed pastures = total forage use, mid-Oct.*

**Stubble Height Sampling**

Stubble height sampling methodology was the same in both years. For each sampling period, the average height of 60 individual western wheatgrass plants was measured (Interagency Technical Reference 1996). Individual plants (grazed and ungrazed) were measured as encountered at approximate 3-m intervals along a transect. An individual western wheatgrass plant was defined as a turf of vegetation occupying a circle at least 5 cm in diameter. Height of the extended green leaf area of each plant was measured to the nearest 0.5 cm after gently placing a ruler in the middle of the turf circle. When a plant was grazed unevenly, we ocularly estimated the average height of the 5-cm turf area. Mean residual stubble height for each sampling area was calculated from the 60 plants, and mean residual stubble height for pastures was calculated as described for paired-plot estimates.

**Statistical Analyses**

We employed a completely randomized design experiment with 2 x 2 factorial arrangement of treatments. Because we measured forage use of western wheatgrass and residual stubble height repeatedly in sampling areas, we used a multivariate repeated measures analysis of variance to test the effects of grazing animal (elk vs elk and cattle), year (1997 vs 1998), and grazing animal x year interaction (P > 0.9). On average, elk had used about 20% (relative use) of western wheatgrass in pastures scheduled for grazing and rest before cattle were released into the study area (Fig. 2A). In rested pastures (elk use), forage use measured after cattle grazing, and at the end of the growing season, averaged 25% (relative use) and 24% (total use), respectively, while corresponding use in grazed pastures (cattle and elk use) averaged 48% (relative use) and 46% (total use). Total forage use averaged 22 percentage points higher in grazed pastures (46%) than in rested pastures (24%) at the end of the growing season.

Relative forage use attributable to elk averaged about 20% before cattle arrived in the study area both years of the study (Fig. 2B). However, forage use measured after cattle grazing and at the end of the growing season averaged 10 and 16 percentage points higher in 1998 than in 1997, respectively.

**Results**

**Forage Use**

Forage use was influenced by type of grazing animal (Fig. 2A; F2,19 = 6.1; P = 0.009) and year (Fig. 2B; F2,19 = 2.9; P = 0.08) and there was no type of animal x year interaction (P > 0.9). On average, elk had used about 20% (relative use) of western wheatgrass in pastures scheduled for grazing and rest before cattle were released into the study area (Fig. 2A). In rested pastures (elk use), forage use measured after cattle grazing, and at the end of the growing season, averaged 25% (relative use) and 24% (total use), respectively, while corresponding use in grazed pastures (cattle and elk use) averaged 48% (relative use) and 46% (total use). Total forage use averaged 22 percentage points higher in grazed pastures (46%) than in rested pastures (24%) at the end of the growing season.

Relative forage use attributable to elk averaged about 20% before cattle arrived in the study area both years of the study (Fig. 2B). However, forage use measured after cattle grazing and at the end of the growing season averaged 10 and 16 percentage points higher in 1998 than in 1997, respectively.

**Residual Stubble Height**

Residual stubble height also was influenced by type of grazing animal (Fig. 3A; F2,19 = 3.6; P = 0.06) and year (Fig. 3B; F2,19 = 32.2; P < 0.0001), and there was no type of animal x year interaction (P > 0.8). Stubble height averaged 14 cm in pastures scheduled for grazing and rest before cattle entered the study area (Fig. 3A). In grazed pastures (cattle and elk use), mean stubble height decreased to 12 cm after cattle grazing and to 10 cm at the end of the growing season, compared with 13 and 12 cm in rested pastures (elk use), respectively, during those same sampling periods. Stubble heights averaged 2 cm lower in grazed pastures (10 cm) than in rested pastures (12 cm) by the end of the growing season.

In 1997, stubble heights, measured before cattle grazing (12 cm) and after cattle grazing (10 cm), averaged 4 and 5 cm lower than respective 1998 stubble heights (i.e., 16 and 15 cm; Fig. 3B). However, stubble height averaged about the same by the end of the growing season for both years of the study (i.e., 12 and 11 cm in 1997 and 1998, respectively).

**Elk and Cattle Grazing Patterns**

Because it is important to discuss both relative and total forage use in relation to corresponding stubble heights across sampling periods, we tabulated results by year and grazing treatment (Tables 1 and 2). Higher use levels occurred after cattle had occupied grazed pastures (cattle and elk use), which typically yielded lower stub-
Both years of the study regardless of grazing treatment (i.e., range = 10-12 cm; Table 1) exceeded levels recommended for semi-arid ranges (e.g., 30-40%, Holechek et al. 1998); however, residual stubble height for western wheatgrass (Table 2) never fell below the 8–10 cm (3–4 in) minimum recommended by the same authors (Holechek et al. 1998). In rested pastures, mean total Elk use (22% in 1997 and 26% in 1998) and end-of-growing-season stubble height (12 cm during both 1997 and 1998) were also within recommended limits (Holechek et al. 1998).

Adhering strictly to utilization or stubble height guidelines while ignoring effects of intensity, frequency, and season of use yields an incomplete picture of grazing impacts (Zhang and Romo 1995, Smith 1998). For example, cattle grazing in each pasture occurred only 19 days/year (intensity, frequency) and after seed set or during dormancy, when western wheatgrass is less vulnerable to herbivory (season of use) (Smith 1998). Pastures grazed by cattle 1 year were rested from cattle the following year (frequency) and received relatively light Elk use (intensity). Because total use in rested pastures was nearly the same in June as in October (Table 1), we concluded that most Elk use occurred early in the growing season when western wheatgrass was in the vegetative stage (season of use). Perennial grasses tend to be more tolerant of grazing during the vegetative stage compared to the reproductive “boot” stage because meristematic tissue is relatively closer to ground (Frost et al. 1994, Smith 1998).

The sampling technique used may also influence the results obtained. One disadvantage of the paired-plot technique is that use estimates are imprecise unless sample size is very large (Klingman et al. 1943). An attempt in 1998 to decrease paired-plot unit variability within sampling areas by individually matching subsamples was ineffective (Bork and Werner 1999). Additionally, Bork and Werner (1999) suggested that the standard practice of zeroing negative utilization values when using the paired-plot technique could contribute to overestimation of forage use on spatially heterogeneous ranges. Negative use values from paired-plot units were zeroed following Werner and Urness (1998). Zeroed paired-plot data in our study were 9 percentage points higher than the sampling technique used may also influence the results obtained. One disadvantage of the paired-plot technique is that use estimates are imprecise unless sample size is very large (Klingman et al. 1943). An attempt in 1998 to decrease paired-plot unit variability within sampling areas by individually matching subsamples was ineffective (Bork and Werner 1999). Additionally, Bork and Werner (1999) suggested that the standard practice of zeroing negative utilization values when using the paired-plot technique could contribute to overestimation of forage use on spatially heterogeneous ranges. Negative use values from paired-plot units were zeroed following Werner and Urness (1998). Zeroed paired-plot data in our study were 9 percentage points higher than

### Discussion

#### Level of Forage Use

Whether the Walker Basin Allotment grazing system provided “proper” forage use depended on the metric used. For example, mean 1998 total use in grazed pastures (61%, Table 1) exceeded levels recommended for semi-arid ranges (e.g., 30-40%, Holechek et al. 1998); however, residual stubble height for western wheatgrass (Table 2) never fell below the 8–10 cm (3–4 in) minimum recommended by the same authors (Holechek et al. 1998). In rested pastures, mean total Elk use (22% in 1997 and 26% in 1998) and end-of-growing-season stubble height (12 cm during both 1997 and 1998) were also within recommended limits (Holechek et al. 1998).

Adhering strictly to utilization or stubble height guidelines while ignoring effects of intensity, frequency, and season of use yields an incomplete picture of grazing impacts (Zhang and Romo 1995, Smith 1998). For example, cattle grazing in each pasture occurred only 19 days/year (intensity, frequency) and after seed set or during dormancy, when western wheatgrass is less vulnerable to herbivory (season of use) (Smith 1998). Pastures grazed by cattle 1 year were rested from cattle the following year (frequency) and received relatively light Elk use (intensity).

Because total use in rested pastures was nearly the same in June as in October (Table 1), we concluded that most Elk use occurred early in the growing season when western wheatgrass was in the vegetative stage (season of use). Perennial grasses tend to be more tolerant of grazing during the vegetative stage compared to the reproductive “boot” stage because meristematic tissue is relatively closer to ground (Frost et al. 1994, Smith 1998).

The sampling technique used may also influence the results obtained. One disadvantage of the paired-plot technique is that use estimates are imprecise unless sample size is very large (Klingman et al. 1943). An attempt in 1998 to decrease paired-plot unit variability within sampling areas by individually matching subsamples was ineffective (Bork and Werner 1999). Additionally, Bork and Werner (1999) suggested that the standard practice of zeroing negative utilization values when using the paired-plot technique could contribute to overestimation of forage use on spatially heterogeneous ranges. Negative use values from paired-plot units were zeroed following Werner and Urness (1998). Zeroed paired-plot data in our study were 9 percentage points higher than

### Level of Forage Use

Whether the Walker Basin Allotment grazing system provided “proper” forage use depended on the metric used. For example, mean 1998 total use in grazed pastures (61%, Table 1) exceeded levels recommended for semi-arid ranges (e.g., 30-40%, Holechek et al. 1998); however, residual stubble height for western wheatgrass (Table 2) never fell below the 8–10 cm (3–4 in) minimum recommended by the same authors (Holechek et al. 1998). In rested pastures, mean total Elk use (22% in 1997 and 26% in 1998) and end-of-growing-season stubble height (12 cm during both 1997 and 1998) were also within recommended limits (Holechek et al. 1998).

Adhering strictly to utilization or stubble height guidelines while ignoring effects of intensity, frequency, and season of use yields an incomplete picture of grazing impacts (Zhang and Romo 1995, Smith 1998). For example, cattle grazing in each pasture occurred only 19 days/year (intensity, frequency) and after seed set or during dormancy, when western wheatgrass is less vulnerable to herbivory (season of use) (Smith 1998). Pastures grazed by cattle 1 year were rested from cattle the following year (frequency) and received relatively light Elk use (intensity).

Because total use in rested pastures was nearly the same in June as in October (Table 1), we concluded that most Elk use occurred early in the growing season when western wheatgrass was in the vegetative stage (season of use). Perennial grasses tend to be more tolerant of grazing during the vegetative stage compared to the reproductive “boot” stage because meristematic tissue is relatively closer to ground (Frost et al. 1994, Smith 1998).

The sampling technique used may also influence the results obtained. One disadvantage of the paired-plot technique is that use estimates are imprecise unless sample size is very large (Klingman et al. 1943). An attempt in 1998 to decrease paired-plot unit variability within sampling areas by individually matching subsamples was ineffective (Bork and Werner 1999). Additionally, Bork and Werner (1999) suggested that the standard practice of zeroing negative utilization values when using the paired-plot technique could contribute to overestimation of forage use on spatially heterogeneous ranges. Negative use values from paired-plot units were zeroed following Werner and Urness (1998). Zeroed paired-plot data in our study were 9 percentage points higher than

**Fig. 3.** Grazing animal (A) and year (B) effects on western wheatgrass stubble height (cm) across 3 sampling periods on the Walker Basin Allotment, central Arizona (SEM = 0.4). Sampling periods were: Before cattle grazing = relative forage use, early/mid-Jun.; After cattle grazing = relative forage use, mid-Jun./early Jul.; End of growing season, or 3 to 4 months after cattle exited grazed pastures = total forage use, mid-Oct.
Elk and Cattle Grazing Patterns

The grazing system did not provide half of the study pastures with complete rest because elk used all pastures both years of the study. In 1997, relative and total elk use in rested pastures remained slightly below the recommended 30 to 40% range during all 3 sampling periods (Table 1). In 1998, the same trend in rested pastures held except there was relatively less elk use before cattle grazing (13%). A decline in 1998 stubble height for both grazed (10 ± 0.6) and rested (12 ± 0.6) pastures at the end of the growing season suggested that some elk use occurred in the study area after cattle grazing (Table 2). However, similar forage use estimates made after cattle grazing, and at the end of the growing season during both 1997 and 1998, suggested that elk did not return to the study area in high enough numbers to significantly increase total forage use in either grazed or rested pastures from June to October (Table 1). We therefore conclude that forage manipulation by cattle did not attract elk to cattle-grazed pastures within the same year. We also conclude that elk use was not influenced by previous year’s cattle grazing, because elk use prior to the arrival of cattle was about twice as high in pastures 1 and 2 as in pastures 3 and 4 both years, regardless of grazing treatment (Table 1). Corresponding residual stubble heights were slightly lower in pastures 1 and 2 compared to pastures 3 and 4 both years (Table 2). Pastures 1 and 2 were near a drainage thought to be used by migrating elk and had more pinyon and juniper cover than pastures 3 and 4. Thus, elk use patterns were apparently more related to preferences for protective cover, topography, and traditional migration patterns than the grazing system’s hypothesized effect on forage regrowth and palatability (Skovlin 1982, Wallace and Krausman 1987, Vavra 1992, Dyke et al. 1998).

Conclusions and Management Implications

Our study provided local knowledge of cattle-elk forage use and stubble height patterns in central Arizona, which is an essential first step for managers to evaluate whether management practices are achieving resource objectives (McIntosh and Krausman 1982, O’Neil 1985, Cook et al. 1998). Forage use data provides a general idea of the level and patterns of large ungulate herbivory (Miller et al. 1994, Smith 1998). Stubble height data complements forage use and other monitoring data because it is correlated with erosion protection, soil moisture retention, forage regrowth potential, and small animal and insect habitat (Hall and Lindenmuth 1998). Although it appears that the Walker Basin Allotment grazing system promotes proper levels of residual vegetation, a more comprehensive rangeland monitoring program is needed to confirm or refute this assertion (Laycock 1998, Smith 1998). Rangeland trend data (e.g., plant species composition, herbaceous and shrub cover, vegetation structure) would help determine long-term sustainability of forage use or residual stubble height levels.

Because elk foraging on the Walker Basin Allotment was evidently affected more by elk habitat preferences than the grazing system, further field investigations are needed. For example, the relationship between elk and cattle forage use and temporal and spatial distribution on the Walker Basin Allotment may differ at higher or lower elevations and result in different elk use patterns. Manipulative experiments at different elevations are needed to determine whether habitat changes induced by the grazing system (i.e., forage quality and quantity) exert more influence on elk at these elevations than other habitat elements like cover and topography (Vavra and Sheehy 1996, Cook et al. 1998).

Elk and other wild ungulates have the freedom to choose foraging sites that best meet their physiological and behavioral needs. Managers designing dual or multi-species grazing systems should consider how intensity and season of livestock grazing, in combination with local level habitat characteristics and animals’ behavioral habits, might influence spatial and temporal movements of wild ungulates (Cook et al. 1998, Unsworth et al. 1998).
